Abstract

Temporal-difference (TD) learning is an important field in reinforcement learning. The most used TD control algorithms are probably Sarsa and Q-Learning. While Sarsa is an on-policy algorithm, Q-Learning learns off-policy. Sutton and Barto (2017) found a way to unify both of them in the $Q(\sigma)$ algorithm. This paper extends the $Q(\sigma)$ algorithm to an online multi-step algorithm using eligibility traces. The new proposed eligibility trace is a weighted average between the eligibility traces usually used for Sarsa(λ) and $Q(\lambda)$. Experiments suggest that the new algorithm called $Q(\sigma\lambda)$ outperforms the classical TD control methods Sarsa and Q-Learning as well as the one-step $Q(\sigma)$ algorithm.

1 Introduction

Reinforcement Learning is a field of machine learning addressing the problem of sequential decision making. It is usually formulated as an interaction of an agent and an environment, which interact over a number of discrete time steps t. At each time point the agent chooses an action A_t from the action space $\mathcal A$ based on the environment's state S_t . The environment takes A_t as an input and returns the next state observation S_{t+1} and reward R_{t+1} . The reward is a scalar numeric feedback signal which quantifies how good an action is.

The agent is thereby following a policy π which is the behavior function and maps a state to action probabilities

$$\pi(a|s) = P(A_t = a|S_t = s).$$
 (1)

Markov-Decision-Processes (MDP) provide the theoretical framework for reinforcement learning. An MDP models state transitions using a probability matrix $P_{ss'}^a = P(S_{t+1} = s' | S_t = s, A_t = a)$. If the interaction between agent and environment ends after a finite number of time steps we call this an episodic task else we speak of a continuing task.

In reinforcement learning the goal is usually to maximize the return G_t , which is the sum of rewards over the lifetime of the agent,

$$G_t = R_{t+1} + \gamma R_{t+2} + \gamma^2 R_{t+3} + \dots = \sum_{k=0}^{T-1} \gamma^k R_{t+1+k},$$
(2)

where $\gamma \in [0, 1]$ is the discount factor and T is the length of the episode or infinity for a continuing task.

 While rewards are short-term signals about the goodness of an action, values represent the long-term value of a state or state and action. The action value function $q_{\pi}(s, a)$ is defined as the expected return taking action a from state s and thereafter following policy π :

$$q_{\pi}(s, a) = \mathbb{E}_{\pi}[G_t | S_t = s, A_t = a].$$
 (3)

Value-based reinforcement learning is concerned with finding the optimal action value function $q*=\max_{\pi}q_{\pi}$. Temporal-difference learning is a class of model-free methods which estimates q_{π} from sample transitions and updates the values using rewards and values of successor actions, i.e. it bootstraps.

When representing the action values as a table we speak of tabular reinforcement learning, else we speak of approximate reinforcement learning if the action value is approximated by a function approximator. For sake of simplicity the following analysis is done for tabular reinforcement learning but can be easily extended to function approximation.

2 TD control algorithms: From Sarsa to $Q(\sigma)$

Sarsa (Rummery and Niranjan (1994)) is a temporal-difference learning algorithm which samples states and actions using an epsilon-greedy policy and then updates the Q values using updates of the form

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha (R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t)).$$
(4)

The term $R_{t+1} + \gamma Q(S_{t+1}, A_{t+1})$ is called the TD target and consists of the reward plus the discounted value of the next state and next action. The term $R_{t+1} + \gamma Q(S_{t+1}, A_{t+1}) - Q(S_t, A_t)$ is then called the TD error. The update rule then corrects the current Q values in the direction of the error between the current estimate and the TD target, where α is the learning rate, which controls how much the values are corrected.

Sarsa is an on-policy method, the TD target uses $Q(S_{t+1}, A_{t+1})$, where A_{t+1} is sampled using the current policy. In general the policy used to sample the state and actions - the so called behaviour-policy μ - can be different from the target policy π , which is used to compute the TD target. If behaviour and target policy are different we call this off-policy learning. An example for an off-policy TD control algorithm is the well known Q-Learning algorithm proposed by Watkins (1989). States and actions are sampled using an exploratory behaviour policy, e.g. an ϵ -greedy policy, but the TD target is computed using the greedy policy with respect to the current Q values. The update rule is therefore

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha \left(R_{t+1} + \gamma \max_{a'} Q(S_{t+1}, a') - Q(S_t, A_t) \right).$$
 (5)

Expected Sarsa generalizes Q-Learning to arbitrary target policies. The update rule is

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha \left(R_{t+1} + \gamma \sum_{a'} \pi(a'|S_{t+1}) Q(S_{t+1}, a') - Q(S_t, A_t) \right).$$
 (6)

You can easily see that Q-Learning is just a special case of Expected Sarsa if π is the greedy policy with respect to Q:

$$\pi(a|s) = \begin{cases} 1 & \text{if } a = \operatorname{argmax} \ Q(s,a) \\ 0 & \text{otherwise} \end{cases}$$
 (7)

Then $\sum_{a'} \pi(a'|S_{t+1})Q(S_{t+1},a')$ is equal to $\max_{a'} Q(S_{t+1},a')$ because all non-greedy actions will have a probability of 0 and the sum reduces to the Q value of the greedy action which is the maximum Q value.

Of course Expected Sarsa could also be used as an on-policy algorithm if the target policy is chosen to be the same as the behaviour policy.

Sutton and Barto (2017) propose a new TD control algorithm called $Q(\sigma)$ which unifies Sarsa and Expected Sarsa. The TD target of this new algorithm is a weighted mean of the Sarsa and Expected Sarsa TD targets, where the parameter σ controls the weighting. When $\sigma=1$ $Q(\sigma)$ is equal to Sarsa, when $\sigma=0$ $Q(\sigma)$ is equal to Expected Sarsa and when using $\sigma=0$ and a greedy target policy $Q(\sigma)$ is equal to Q-Learning. For intermediate values of sigma new algorithms are obtained, which can achieve better performance (Asis et al. (2017)).

The update rule for $Q(\sigma)$ is

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha(R_{t+1} + \gamma(\sigma Q(S_{t+1}, A_{t+1}) + (1 - \sigma) \sum_{a'} \pi(a'|S_{t+1})Q(S_{t+1}, a')) - Q(S_t, A_t)).$$
(8)

3 Multi-step Methods and Eligibility Traces

The TD methods presented so far are one-step methods, which use only rewards and values from the next step t+1. These can be extended to look into a more distant time horizon, e.g. to incorporate data from two steps away. A two-step Sarsa update could then be

$$Q(S_t, A_t) = Q(S_t, A_t) + \alpha \left(R_{t+1} + \gamma R_{t+2} + \gamma^2 Q(S_{t+2}, A_{t+2}) - Q(S_t, A_t) \right). \tag{9}$$

Of course instead of the two-step return we could also use any n-step return defined by

$$G_{t:t+n} = R_{t+1} + \gamma R_{t+2} + \dots + \gamma^n R_{t+n} + \gamma^{n+1} Q(S_{t+n+1}, A_{t+n+1})$$
(10)

as a TD target.

N-step versions of Q-Learning and Expected Sarsa can be obtained similarly, e.g. the n-step return for Q-Learning is defined by

$$G_{t:t+n} = R_{t+1} + \gamma R_{t+2} + \dots + \gamma^n R_{t+n} + \gamma^{n+1} \max_{a} Q(S_{t+n+1}, a).$$
(11)

Sutton and Barto (2017) and Asis et al. (2017) also propose an n-step version of $Q(\sigma)$.

N-step returns can also be averaged to the so called λ -return defined by

$$G_t^{\lambda} = (1 - \lambda) \sum_{n=1}^{T-t-1} \lambda^{n-1} G_{t:t+n} + \lambda^{T-t-1} G_t.$$
 (12)

For $\lambda=0$ the λ -return is equal to the one-step Sarsa target, for $\lambda=1$ it is equal to a the empirical return, which is used as a TD target in Monte Carlo learning.

N-step algorithms have the advantage that they make use of data of the following n steps. A disadvantage is that n-step returns can only be computed after n steps, so a value can only be adjusted after the next n rewards have been observed. When using G_t^{λ} as a TD target the algorithm can only update the value function after the end of the episode, because the last n-step return can only then be computed, and cannot be applied to continuing problems at all. When all updates to a value function are made at the end of an episode, we call this an offline algorithm, in contrast to online algorithms,

Updating the value of a state towards rewards obtained at later time steps is called the forward-view. Often there exists a computationally advantageous backward-view, which assigns the current error backwards to previously visited states using eligibility traces. Using this backward view we can obtain online multi-step algorithms for the algorithms presented so far.

An eligibility trace is a scalar numeric value for each state-action pair. Whenever a state-action pair is visited its eligibility is increased, if not, the eligibility fades away over time. State-action pairs visited often will have a higher eligibility than those visited less frequently and state-action pairs visited recently will have a higher eligibility than those visited long time ago.

Different eligibility traces are proposed in the literature. Two kinds are especially commonly used: the accumulating trace and the replacing trace (Singh and Sutton (1996)).

The accumulating trace uses an update of the form

$$E_{t+1}(s,a) = \begin{cases} \gamma \lambda E_t(s,a) + 1, & \text{if } A_t = a, S_t = s\\ \gamma \lambda E_t(s,a), & \text{otherwise.} \end{cases}$$
(13)

Whenever taking action A_t in state S_t the eligibility of this pair is increased by 1 and for all states and actions decreased by a factor $\gamma\lambda$, where λ controls the trade-off with a one-step TD method at one extreme and Monte Carlo at the other extreme. Higher λ values assign the current TD error back over longer time intervals than lower λ values.

The replacing trace is similar to the accumulating trace but the eligibility has an upper bound of 1. It is defined by

$$E_{t+1}(s,a) = \begin{cases} 1, & \text{if } A_t = a, S_t = s \\ \gamma \lambda E_t(s,a), & \text{otherwise.} \end{cases}$$
 (14)

The replacing trace has the advantage that the eligibility cannot be greater than 1, therefore it can be more stable than the accumulating trace when episodes are very long and states are revisited frequently. Then the eligibility using accumulating traces would become very large which can lead to instability (Singh and Sutton (1996)).

The update rule using eligibility traces is then modified to

$$Q(s,a) = Q(s,a) + \alpha \delta E_t(s,a) \quad \forall s \in \mathcal{S}, a \in \mathcal{A}$$
(15)

with δ denoting the TD error. The corresponding algorithm using the one-step Sarsa TD error and an update using eligibility traces is called Sarsa(λ). Though it looks like a one-step algorithm, it is in fact a multi-step algorithm, because the current TD error is assigned back to all previously visited states and actions weighted by their eligibility.

A natural idea is to combine replacing and accumulating trace into a weighted average.

Then the eligibility trace update is

$$E_{t+1}(s,a) = \begin{cases} (1-\beta)(\gamma \lambda E_t(s,a) + 1) + \beta * 1, & \text{if } A_t = a, S_t = s \\ (1-\beta)\gamma \lambda E_t(s,a) + \beta \gamma \lambda E_t(s,a), & \text{otherwise.} \end{cases}$$
(16)

This can be simplified to

$$E_{t+1}(s,a) = \begin{cases} (1-\beta)(\gamma \lambda E_t(s,a)) + 1, & \text{if } A_t = a, S_t = s\\ \gamma \lambda E_t(s,a), & \text{otherwise.} \end{cases}$$
(17)

The factor β now controls the weighting, with $\beta=0$ being the usual accumulating trace and $\beta=1$ being the replacing trace. In the tabular case this is equal to the so called Dutch trace proposed by van Seijen et al. (2015).

How can eligibility traces used for off-policy TD algorithms, so we can obtain a λ -version of Q-Learning and Expected Sarsa? Naive $Q(\lambda)$ uses the same eligibility updates as described before, ignoring that learning is off-policy. Watkin's $Q(\lambda)$ uses the same updates as long as the greedy action is chosen by the behaviour policy, but sets the Q values to 0, whenever a non-greedy action is chosen assigning credit only to state-action pairs we would actually have visited if following the target policy π and not the behaviour policy μ . More generally the eligibility is weighted by the target policy's probability of the next action. The update rule is then

$$E_{t+1}(s,a) = \begin{cases} (1-\beta)(\gamma \lambda E_t(s,a)\pi(A_{t+1}|S_{t+1})) + 1, & \text{if } A_t = a, S_t = s\\ \gamma \lambda E_t(s,a)\pi(A_{t+1}|S_{t+1}), & \text{otherwise.} \end{cases}$$
(18)

Whenever an action occurs, which is unlikely in the target policy, the eligibility of all previous states is decreased sharply. If the target policy is the greedy policy, the eligibility will be set to 0 for the complete history.

The final step is to propose a new kind of eligibility trace to extend the $Q(\sigma)$ algorithm to an online multi-step algorithm.

Recall that the one-step target of $Q(\sigma)$ is a weighted average between the on-policy Sarsa and off-policy Expected Sarsa targets weighted by the factor σ :

$$\delta_t = R_{t+1} + \gamma(\sigma Q(S_{t+1}, A_{t+1}) + (1 - \sigma) \sum_{a'} \pi(a'|S_{t+1}) Q(S_{t+1}, a')) - Q(S_t, A_t)$$
(19)

The natural idea is then to weight the eligibility accordingly with the same factor σ . The eligibility will then be a weighted average between the on-policy eligibility used in Sarsa(λ) and the off-policy eligibility used in $Q(\lambda)$. Then the eligibility trace is updated at each step by

$$E_{t+1}(s,a) = \begin{cases} (1-\beta)(\gamma \lambda E_t(s,a)(\sigma + (1-\sigma)\pi(A_{t+1}|S_{t+1}))) + 1, & \text{if } A_t = a, S_t = s\\ \gamma \lambda E_t(s,a)(\sigma + (1-\sigma)\pi(A_{t+1}|S_{t+1})), & \text{otherwise.} \end{cases}$$
(20)

When $\sigma=0$ the one-step target of $Q(\sigma)$ is equal to the Sarsa one-step target and therefore the eligibility update reduces to the standard on-policy eligibility trace update (accumulate or replace trace according to β). When $\sigma=1$ the one-step target of $Q(\sigma)$ is equal to the Expected Sarsa target and accordingly the eligibility is weighted by the target policy's probability of the current action. For intermediate values of σ the eligibility is weighted in the same way as the TD target.

The n-step $Q(\sigma)$ algorithm presented by Sutton and Barto (2017) and Asis et al. (2017) has the usual disadvantage of n-step algorithms that it needs to store TD errors at each step and can only update the value function after n steps. The newly proposed algorithm, which we call $Q(\sigma\lambda)$ on the other side can learn online and does not need to store all TD errors. Of course σ or λ can also be varied over time, e.g. depending on states or actions.

Pseudocode for tabular episodic $Q(\sigma\lambda)$ is given in Algorithm 1. This can be easily extended to function approximation using one eligibility per weight of the function approximator and to continuing tasks.

4 Experiments

In this section the performance of the newly proposed $Q(\sigma\lambda)$ algorithm will be tested on different tasks.

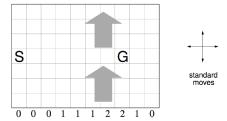

Figure 1: The windy gridworld task. The goal is to move from the start state S to the goal state G while facing an upward wind in the middle of the grid, which is denoted in the numbers below the grid. Described by Sutton and Barto (1998).

Figure 2: Windy gridworld results. Performance of $O(\sigma \lambda)$ for different values of σ and λ . For higher values of λ learning is faster and Sarsa learns faster than Q-Learning. Steps per episode are averaged over 100 runs.

Windy Gridworld

The windy gridworld is a simple navigation task from Sutton and Barto (1998). The goal is to get from a start state to a goal state using the standard actions, moving left, right, up or down. In each column of the grid the agent is moved a certain number of columns upward. When an action would take the agent outside the grid, the agent is placed in the nearest cell inside the grid. The task is treated as an undiscounted episodic task with a reward of -1 for each transition. Figure 1 visualizes the gridworld.

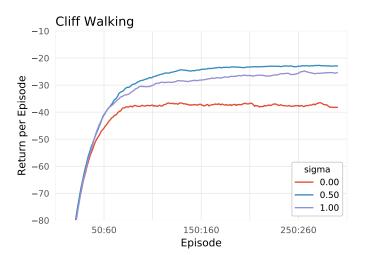

Figure 3: The cliff walking gridworld.

safe path

optimal path

Figure 4: Results on the cliff walking task.

Experiments were conducted using an ϵ -greedy behavior policy with $\epsilon = 0.1$ for different values of σ , λ and β . The learning rate α was set to 0.1 and accumulating eligibility traces ($\beta = 0$) have been used. The target policy of the Expected Sarsa target was chosen to be the greedy policy with respect to Q, i.e. a Q-Learning target.

Figure 2 shows that learning occurs faster if λ is higher, so the multi-step method $Q(\sigma\lambda)$ dominates one-step $Q(\sigma)$ for different values of σ including Sarsa, Q-Learning and also for intermediate values of σ .

Also Sarsa (Q(1)) performs initially better than $Q(\sigma)$ with lower σ values, e.g. Q-Learning (Q(0)). This is not surprising because the eligibility trace will be multiplied with the target policy's probability, which is 0 when a non-greedy action occurs. So for a non-greedy action the eligibility will be updated by

$$E_{t+1}(s,a) = \gamma \lambda \sigma E_t(s,a) \quad \text{if } A_{t+1} \neq \underset{a}{\operatorname{argmax}} Q(S_{t+1},a), \tag{21}$$

so it will be reduced by the factor σ at each step. Q-Learning in the extreme sets the eligibility trace to 0 resulting in one-step learning.

Cliff Walking

Cliff Walking is also a gridworld navigation task, but with a cliff in the lower part of the grid. Stepping into the cliff results in a negative reward of -100.

I've tested $Q(\sigma\lambda)$ on this task using an ϵ -greedy behavior and a greedy target policy for different values of σ . The learning rate α was set to 0.5, λ was set to 0.5 and the task was treated as an undiscounted task. 100 runs each with 300 episodes were conducted.

Figure 4 show that an intermediate value of σ performed best, followed by Sarsa and Q-Learning performed worst. Sutton and Barto (1998) observe that Sarsa has initial better performance on this task because it learns the safe path at the top of the grid, while Q-Learning learns the optimal path, which results in falling into the cliff, because of the ϵ -greedy behavior policy followed. Q(0.5) which performed best also learns a safe path.

Figure 5: The Mountain Car task as described by Sutton and Barto (1998). The goal is to move an under-powered car from the valley to the top of the right mountain.

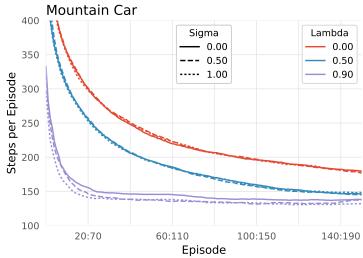

Figure 6: Performance of $Q(\sigma\lambda)$ on the Mountain Car task for different values of σ and λ . A moving average containing 50 episodes was applied to smooth the curves. Results were averaged over 100 runs.

4.3 Mountain Car

MOUNTAIN CAR

The Mountain Car task as described by Sutton and Barto (1998) is a classic control task with a continuous state space. The goal is to move an under-powered car as fast as possible from the valley up a mountain. The state is characterized by the position and velocity of the car and there are three actions ("push left", "do nothing", "push right"). Figure 5 visualizes the environment. For each step the agent receives a reward of -1 until the goal state is reached and we treat this as an undiscounted task ($\gamma=1$). Because the state space is continuous function approximation needs to be used. Therefore the action value function was approximated using tile coding, i.e. using Sutton's tile coding software version 3 with 8 tilings and max_size = 4096.

Then $Q(\sigma\lambda)$ with linear function approximation has been applied. The behavior policy was for all experiments an ϵ -greedy policy with $\epsilon=0.1$, the learning rate was set to 0.1 and accumulating eligibility traces ($\beta=0$) have been used. The target policy of the Expected Sarsa target was chosen to be the greedy policy with respect to Q, i.e. a Q-Learning target. All results were averaged over 100 runs. Figure 6 shows the results on the Mountain Car task for different values of σ and λ .

5 Conclusions

This paper has presented a new multi-step version of the $Q(\sigma)$ algorithm called $Q(\sigma\lambda)$, which combines Sarsa and Q-Learning. It uses an eligibility update to allow online learning as in Sarsa(λ). The eligibility trace proposed is a weighted average between the classical on-policy trace used for Sarsa and the off-policy trace used for Q-Learning and other off-policy algorithms. It also combines replacing and accumulating traces into one trace. Empirical results

Unifying Q-Learning and Sarsa with Eligibility Traces suggest that the new $Q(\sigma\lambda)$ algorithm outperforms classical Sarsa(λ) and $Q(\lambda)$ as well as the one-step $Q(\sigma)$ on different References Asis, K.
